Gentlemen:

Contract NAS 8-11964

Enclosed are the final reports on the subject contract. The report is entitled "Gas-Pressure Bonding of Beryllium Gyro and Stabilized Platform Components".

We have forwarded to you the following machined items:

- 1. One inner gimbal
- 2. Three sleeves
- 3. Three air-bearing sleeves
- 4. Three inner cylinders
- 5. Three inner cylinder covers.

These items complete the requirements under the referenced contract.

We hope the information contained in this report is sufficient for your needs. If there are any further questions, please contact us.

Very truly yours,

Hugh D. Hanes

GAS-PRESSURE BONDING OF BERYLLIUM GYRO AND STABILIZED PLATFORM COMPONENTS

рy

H. D. Hanes and P. J. Gripshover

SUMMARY

This study was conducted to prepare machining preforms of beryllium gyro and stabilized platform components by gas-pressure bonding and to prove feasibility by final machining components from these preforms. The components which were prepared for the ST-124 gyro were:

- 1. Stabilized platform gimbal
- 2. Sleeve
- 3. Air-bearing sleeve
- 4. Inner cylinder
- 5. Inner cylinder cover.

The approach for preforming these components had previously been developed in other NASA contracts.

Minor discrepancies occurred on some of the components but were judged satisfactory in most cases by the Technical Monitor. Only one of the twelve air-bearing components was lost because of an inclusion on critical surfaces which is well below the rejection rate normally experienced with conventional beryllium. The report contains the inspection reports from the machining vendors.

INTRODUCTION AND BACKGROUND

This is the final report on research performed on NASA Contract NAS 8-11961. The active contract period extended from January 1, 1966, until May 31, 1967 although the contract was initially approved in June, 1965. This program was funded by the National Aeronautics and Space Administration, George C. Marshall Space Flight Center. The Program Monitor was Mr. Richard H. Tuggle of the Astrionics Laboratory. The overall objective of the program was to fabricate and finish machine various gyro and stabilized platform components from the Saturn ST-124-M guidance system. The gas-pressure-bonding process was used to fabricate preforms from beryllium powder. Then, conventional machining processes used for beryllium gyro components were utilized to finish the parts to specified shapes. Development of the gas-pressure-bonding process for fabricating the machining preforms was performed under Contract NAS 8-11403 and NAS 8-11559. The results of these studies have been previously reported to NASA, and one of the contracts has been reported in the open literature in the report NASA-CR-58256.

This program was initially conceived to fabricate six experimental stabilized platform gimbals. However, as work proceeded, the project was modified to include some of the gyro and accelerometer components fabricated under previous studies. The following is a list of items which were to be gas-pressure bonded and machined to final configurations.

- 1. One beryllium ST-124-M inner gimbal.
- 2. Three beryllium inner cylinders.

- 3. Three beryllium inner cylinder covers.
- 4. Three gyro sleeves.
- 5. Three accelerometer sleeves.

In addition, nine machining blanks of Items 2 through 5 were to be supplied to NASA. These components were preformed from beryllium powder by the gas-pressure-bonding process. Following densification, they were machined to final configurations as specified by drawings supplied by NASA.

Gas-pressure bonding has been shown to be feasible as a means for compacting beryllium components into semi-finished shape. In this manner, machining costs and material losses are minimized so parts can potentially be made cheaper. Also, because of the higher pressure utilized in the pressing operation, the parts are pressed to near theoretical density. There is normally no residual porosity in these parts, thereby minimizing losses due to these causes. Finally, beryllium produced in this manner has been shown to have higher mechanical properties than conventionally hot-pressed block.

The process for preforming these parts had already been developed under the specified contract. Minor modifications were made in tooling to provide sufficient clean-up stock in some components because of minor machining problems previously experienced. However, the same tooling with these minor modifications was utilized to fabricate the preforms in this study. Therefore, virtually no development work was done in this program but rather proof of the process was shown by making the required components and machining them to final actual shapes. The objectives of the program have been met in full, and all of the components have been supplied to NASA.

This report will summarize all of the work done to produce the components listed above. In certain instances, slight deviations from the specifications were experienced, and these deviations are noted in the text of the report. Each individual component is discussed separately, and this discussion includes a brief resume of the fabrication process as outlined in previous reports. Appended to this report are dimensional certifications supplied by the two machining vendors, Barden-Leemath Corporation of Woodbury, Long Island, New York, and American Beryllium Company of Sarasota, Florida.

RESULTS

Inner Gimbal

Fabrication Method

The fabrication method for preforming the inner gimbals by gaspressure bonding has been described in detail in the final report issued under Contract NAS 8-11559. This report, entitled "Fabrication of Beryllium Stabilized Platform Components by Gas-Pressure Bonding", was issued February 2, 1966. The beryllium powder was initially preformed by cold hydrostatic pressing in a shaped latex bag. The internal cavities in this component were formed by porous copper mandrels which could then be selectively leached from the beryllium in HNO₃ after densification. Porous mandrels were used to allow uniform densification during both cold and hot isostatic pressing.

Prior to loading, the hydropressing bag was vacuum formed into an accurately constructed loading jig. The porous mandrels were placed in positions which had been mathematically predetermined. The assembly was de-aired and pressed at 60,000 psi which yielded approximately 75 percent of theoretical density. The part was pressed in a sodium-chloride pressure-transmitting layer which allowed the complex geometry to be sealed into a cylindrical mild-steel container. The part was hot dynamically outgassed at 1000 F prior to compaction. Gas-pressure bonding for this and all the other parts was accomplished at 1400 F and 10,000 psi. After densification, the pressing container was stripped from the part and the sodium chloride removed by dissolving in water. The copper mandrels were leached from the beryllium block, leaving the cavities intact.

Preforming of Inner Gimbals on Current Studies

During this study, three inner gimbal blanks were gas-pressure bonded. Techniques described above and in the previous report were utilized in this study. No modification of the tooling and methods were required in this program. Figure 1 shows one of the machining blanks after gas-pressure bonding.

Of the three inner gimbal preforms pressed, only one was deemed satisfactory for finish machining. The second component showed cracking of the pressing around one of the cavities for mounting of the gyro sleeve. This cracking was attributed to a differential and thermal expansion between the copper mandrel and the beryllium preform. The beryllium in releasing

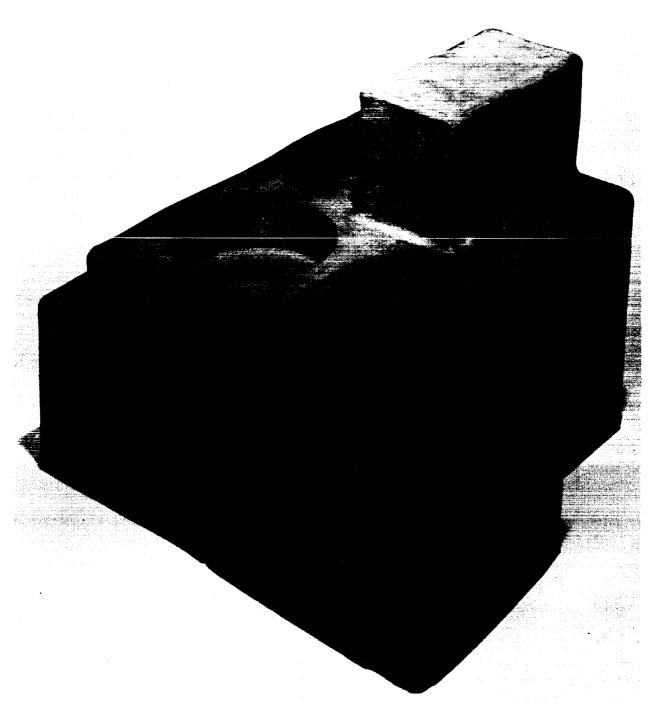

FIGURE 1. MACHINING BLANK OF THE INNER GIMBAL

its bond from the copper mandrel apparently cracked. The third preform failed during the gas-pressure-bonding operation. A leak in one of the welds in the gas-pressure-bonding container caused the differential pressure to be negated during the bonding operation. This can was repaired and the entire assembly submitted to the operation a second time but a crack had appeared in the preform which would not allow it to completely densify in the area in question. At this time, it was deemed most expedient by the Technical Monitor to discontinue work on the inner gimbal preforms.

Machining of the Inner Gimbal

The one inner gimbal blank prepared in this study was successfully machined to finish specifications as shown in Figure 2. This illustrates the fully machined component produced from the gas-pressure-bonded blank. Although there were minor discrepancies which occurred in the machining of this component, it is felt that the resultant part will be usable.

The first problem experienced by the machining vendor was in the design of the gas-pressure-bonded blank itself. After the part was laid out for finish machining, it was noted there was insufficient stock for clean-up in one surface adjacent to the trunnion mount. The lack of material was inadvertently designed in the machining blank itself and was not a result of the fabrication operation. However, since it was on a non-critical surface, the Technical Monitor deemed that the component would be acceptable with this monor deficiency in it.

When machining was initiated on this component by the Barden-Leemath Corporation, it was felt that there was a tendency for excessive

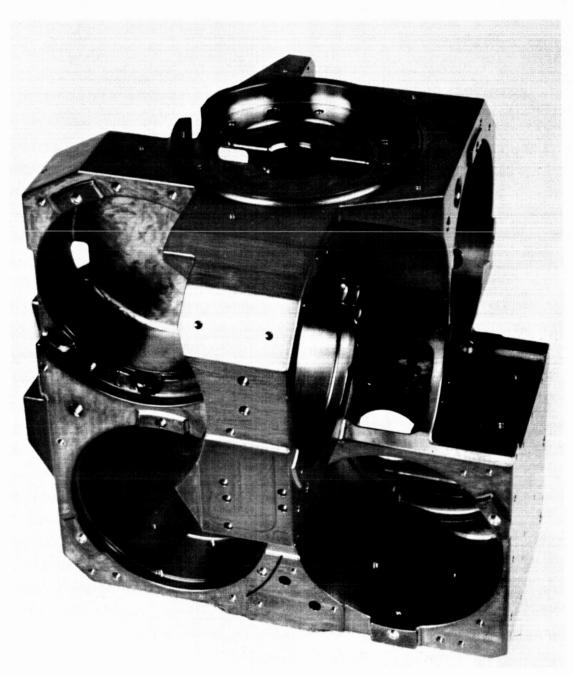

FIGURE 2. INNER GIMBAL AFTER FINAL MACHINING

chipping on the exit areas of the machining surface. This was, however, only noted during the initial cut on the part. When the as-pressed surface was removed from the part, machining appeared to proceed at a normal rate. In reviewing the fabrication process, it was noted that a copper foil vapor barrier was placed around the beryllium preform prior to pressing into the sodium chloride pressure transmitter. It is felt that reaction caused by diffusion of the copper into the beryllium preform resulted in a solid-solution strengthening of the beryllium. This also embrittled the beryllium, making machining of the outer surface more difficult. However, once the diffusion layer was removed from the component, machining proceeded at the normal rate. In future fabrication runs, if a copper vapor barrier were to be used, it would seem advisable to chemically mill the component before machining, thereby removing the difficult-to-machine skin from the beryllium blank.

A third problem was noted with this component during annealing after the rough-machining operation. The specification requires that the part be stress relieved at 1450 F prior to the final machining cut. After the stress-relieving operation, it was noted that dimensions of the rough-machined beryllium blank had slightly changed. Concurrent studies at Battelle on another program had indicated there was a slight loss-in-density problem after heating to relatively high temperatures following the gas-pressure-bonding operation. This has been attributed to lack of complete outgassing of gas-pressure-bonded beryllium prior to the pressing operation. Included gases in the microstructure resulted in a slight loss in density

and subsequent swelling. This loss in density in gas-pressure-bonded beryllium is normally less than 1/2 percent at 1450 F. There normally is no change in mechanical properties accompanying this.

After the change in dimensions was noted, the part was given a second stress-relieving treatment at the same temperature, and this time there was no growth noted in the machining blank. Since none of the machining of the critical dimensions had yet occurred, it was possible to save the part and proceed with the final machining operation. There are no dimensional discrepancies on this component in the critical-surface areas. Dimensional certification of the part is contained in Appendix A of this report.

Gyro Sleeve Fabrication

Basic Fabrication Approach

The gyro sleeve is first preformed by drawing a rubber bag into a vacuum form of proper configuration. Then, the beryllium powder is vibratory packed into position around a leachable copper mandrel. The entire composite is then hydrostatically pressed to form the beryllium powder in a single-piece shape approximating the final machined component. The protrusions on the external surface of this component are pressed inwardly to the part. Following green preforming, the component is pressed into a sodium chloride pressure-transmission layer which will allow final compaction of the component in a simple cylindrical bonding container.

After canning the components, the entire composite is hot dynamically outgassed. Then, the evacuation stem is sealed closed and the part gas-pressure bonded at 1400 F. Removal of this component from the bonding container is similar to that of the inner gimbal. The sodium chloride pressure-transmission layer is dissolved in water, and the copper mandrel which defines the bore of the component is dissolved in nitric acid.

Fabrication of Gyro Sleeve Preforms

Following the procedure outlined above, twelve preforms of the gyro sleeve were fabricated. No problems were experienced in the production of these particular components. After gas-pressure bonding, all of the parts were dimensionally analyzed, and three of the components were forwarded to the machining vendor. The other nine were shipped to Marshall Space Flight Center for their evaluation.

Dimensional evaluation revealed that the exterior surface of the components was close to the required finished dimension. Therefore, the three largest components were selected for finish machining by the vendor to allow sufficient room for setup. Of the nine components supplied to NASA, clean-up might be difficult on the exterior surface. Density measurements on the fabricated components indicated that essentially all of the parts were of full theoretical density. It should be noted that no dimensional changes were noted on the parts machined by the vendor after stress relieving. Also, no machining difficulties were experienced in this material. Figure 3 demonstrates a typical gyro sleeve machining blank produced by gas-pressure bonding.

FIGURE 3. GAS-PRESSURE-BONDED GYRO-SLEEVE MACHINING BLANK

Machining of Gyro Sleeves

Finish machining of the gyro sleeves was accomplished by the American Beryllium Company of Sarasota, Florida. Figure 4 shows one of the gyro sleeves after final machining. Of the three gyro components which were finish machined, only one of them had dimensional discrepancies. The counter sink area for the air holes on the external surface of this cylinder was machined too deeply in one case. However, it was deemed by the Technical Monitor that this would not affect the operation of the component so it was deemed acceptable.

The third component originally forwarded to the machining vendor was rough machined to the point where the internal bore of the part was to be lapped. At this time, it was noted there were spots of apparent porosity on the surface of the component. Xygloing the part at the vendor's site confirmed the presence of porosity in this particular spot. The component was again viewed at Battelle, and it was deemed unaccessible. Therefore, a replacement blank was forwarded to the machining vendor. It should be noted that during the fabrication of all the components in this program this was the only specimen that was rejected because of porosity on a critical surface.

Prior to shipment of the make-up component to the machining vendor, rough machining was done at Battelle to ascertain that sufficient material would be available for finish machining the external cylindrical surface. As was previously noted, there was very little clean-up left on the external surface of the gyro sleeve preforms. Since it was doubtful

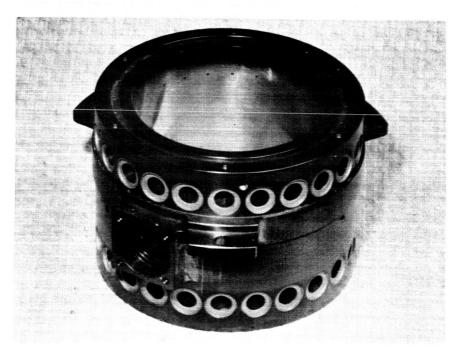

FIGURE 4. GYRO SLEEVE AFTER FINISH MACHINING

that this part could be cleaned up on the external surface, it was deemed expedient to finish this component by hand. The critical surfaces could be machined, and this would not interfere with the operation of the component. Therefore, to provide a complete set of gyro sleeves for testing at NASA, the third component was accepted with insufficient clean-up on the external cylindrical surface.

Certification of the dimensions of these components are contained in Appendix B, and it can be noted that there are no deviations except those noted in the text of the report.

Accelerometer Sleeves

Description of Fabrication Process

The basic approach utilized to fabricate these components was that of bonding green-pressed pellets onto the surface of the green-pressed right circular cylinder during densification. The main body of the accelerometer sleeve was pressed from beryllium powder around a leachable copper mandrel. Then, the pellets to form the trunnions were pressed in a separate operation. The bonding container was fabricated in such a manner as to include space for the extensions on the external surface of the cylinder.

Hot dynamic outgassing and gas-pressure bonding were done at the same conditions previously noted. After densification, the mild-steel bonding containers were removed by pickling in nitric acid. Copper mandrels

were also removed in this manner. In the past, insufficient stock was provided on the exterior surface of the component to allow clean-up at the base of the trunnions. However, compensations were made in existing tooling to allow sufficient stock for final clean-up in the parts in this study.

Preforming of Machining Blanks

Twelve machining blanks of the accelerometer sleeve were fabricated in the manner listed above. Of the components densified, there were no problems experienced with either lack of densification or cracking of the preforms. Measurements indicated there would be sufficient stock for machining the required specimens from the blanks densified. Immersion density measurements revealed complete densification of these components.

Of the twelve specimens densified, nine were shipped to NASA in the as-pressed condition for their evaluation. The other three were shipped to the American Beryllium Company for machining to final configuration. Figure 5 shows a gas-pressure-bonded preform of the accelerometer sleeve.

Machining of the Accelerometer Sleeves

During machining of these components, there were no materials defects noted on any of the critical surfaces. Sufficient stock was present to allow complete finishing of the accelerometer sleeves. There were no dimensional discrepancies in the finished parts as noted in Appendix C. Figure 6 shows an example of the accelerometer sleeve after finish machining.

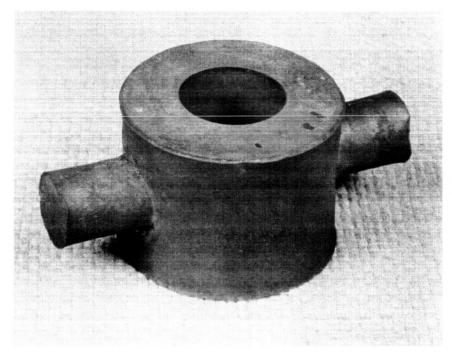

FIGURE 5. AS-PRESSED BLANK OF THE ACCELEROMETER SLEEVE

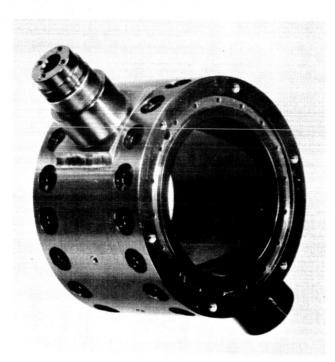

FIGURE 6. MACHINED ACCELEROMETER SLEEVE

One procedural discrepancy was experienced during machining of this component. One of the mounting trunnions at the sleeve has a 1-mil increase in diameter near the body of the sleeve itself. Inadvertently, during the finishing operation, the machinist neglected to allow sufficient stock for this step. To bring the part back into specification, American Beryllium had an electroless nickel plating applied to the surface of the trunnions on Specimens 2 and 3. After performing this operation, the part was finished within the specified dimensions. All three of these finished components have been forwarded to NASA for their evaluation.

Fabrication of Inner Cylinders

Discussion of Approach

The inner cylinders were fabricated from pieced components which were preformed from beryllium powder. The main body of the inner cylinder was pressed onto a copper mandrel. The extension at the top was preformed as a separate button. This part was canned in a container which conformed to the external surface of the component. An extension was provided in the upper end of the container for the small protrusion on the component.

These components were again processed by the same parameters already reported. After densification, the mild-steel cans and the copper mandrels were removed by leaching in nitric acid. Since parts had successfully been prepared from existing tooling in the past, there was no need to modify the tooling for the work done on the current job.

Fabrication of Inner Cylinder Preforms

As previously noted, the loading fixtures were the same configuration as had been previously utilized. However, the internal cavity configuration was changed from the double taper originally pressed to a hemispherical end in the new design. This required altering of the mandrels but did not change the cross section of the loading fixture.

All of the twelve components required for this task of the study were successfully pressed. No problems were experienced with the random cracking as noted in some of the previous specimens. Measurements indicated there was sufficient stock on all of the specimens pressed to machine the specimens to configuration. Density, which was checked by immersion techniques, was found to be 1.865 (essentially full theoretical) in all of the components. Three parts were randomly selected for final machining, and the other nine were forwarded to NASA for their evaluation. Figure 7 shows one of the machining blanks of the inner cylinder produced by gas-pressure bonding.

Final Machining of Inner Cylinders

Certification sheets of the final machined dimensions of the inner cylinders are listed in Appendix D. Machining of these components was accomplished by American Beryllium Company, and there were no problems encountered during the performance of the operation. The finished components were shipped to NASA for final evaluation.

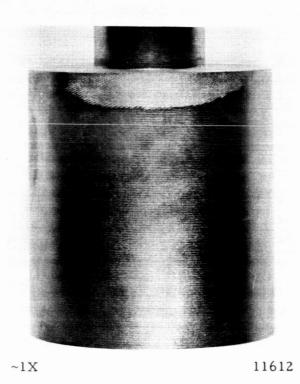

FIGURE 7. GAS-PRESSURE-BONDED INNER CYLINDER

Inner Cylinder Covers

Fabrication Approach

The basic gas-pressure-bonding approach utilized for these components is identical to that utilized for the inner cylinders themselves. The only difference is that the body of the cover is somewhat shorter, and more stock has to be allowed in the region of the legs which support the gyro. Previously, there had been very few problems associated with fabricating these components. Slight problems had been experienced with allowing sufficient stock over the region of the arms to allow complete clean-up of the finished specimen.

Fabrication of the Machining Blanks

One change was noted in the overall dimensions of this component as compared to those previously fabricated. The bottom of the cover was altered to include a spherical radius rather than the tapers previously experienced. Because of this, slight modification of the pressing tooling was necessary. Also, the diameter of the body was increased slightly to allow sufficient clean-up stock on the external cylindrical surface. With these minor modifications, there were no problems experienced in fabricating these components.

After outgassing at 1000 F prior to final closure of the pressing container, the specimens were gas-pressure bonded at 1400 F as was the case for the other parts in this study. The can and mandrel were removed by

leaching in nitric acid. Evaluation of the components revealed sufficient stock for machining the desired shape from these preforms. Immersion density checks revealed full densification in all cases. Figure 8 demonstrates one of the as-pressed machining blanks. These parts were finish machined by Barden-Leemath Corporation.

Machining of Inner Cylinder Covers

Dimensional discrepancies were noted on Parts 1 and 2 of the inner cylinder covers. These discrepancies were discussed with the Project Monitor and, with the exception of the thickness of the gyro mounting arms, were all accepted. It was necessary to alter the width and thickness of the gyro support arms on both pieces to be within .0005 in. of each other on each side. This was done to conform with the minimum dimension noted in the letter reproduced in Appendix E.

One comment from the machining vendor is worthy of note in this section of the study. Because of the hemispherical cross section required in the bottom of this component, it was necessary to generate this surface by electron-discharge machining. Otherwise, it would be necessary to generate the surface on a three-axis milling machine. The machinist noted that the pilot hole in this case was not beneficial to the machining operation because he could not keep an even pressure in the coolant until his tool was well inserted into the pilot hole. Therefore, it took him more time to machine the cavity by this method than it would have in a solid piece of block. Therefore, the value of preforming the part in this manner is somewhat questionable.

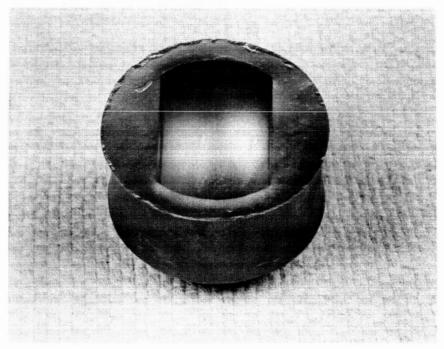

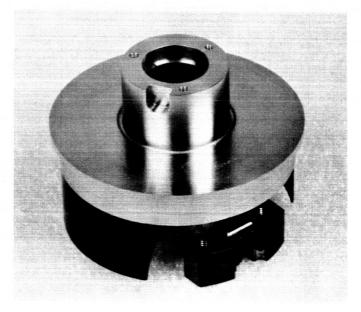

FIGURE 8. AS-PRESSED INNER CYLINDER COVER BLANK

Figure 9 shows one of the final machined inner cylinder covers. Except for the discrepancies previously noted, there were no further problems encountered with these components. They have been forwarded to NASA for the utilization and evaluation.

CONCLUSIONS

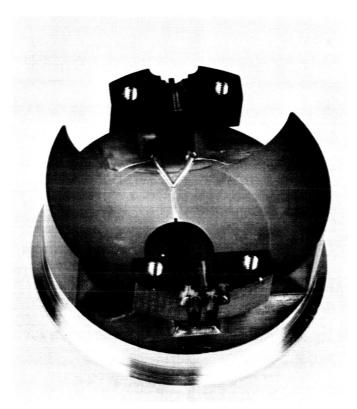

On the basis of the results previously discussed, the following conclusions can be reached in this study.

- 1. The gas-pressure-bonding technique was shown to be a feasible method for fabricating all of the parts in this study as evidenced by the completion of all of the components required.
- 2. Higher-quality material with less defects due to inclusions or porosity is produced by gas-pressure bonding as evidenced by the fact that only one out of twelve finish machined parts was rejected because of material defects.
- 3. A near-finished-dimension inner cylinder cover blank is not practical to fabricate by gas-pressure bonding for the reasons already given in the text.
- 4. The initial machining characteristics of the inner gimbals were worse than expected because of the diffusion of the copper barrier vapor into the surface. However, no problems were experienced after the surface skin was removed, and the machinability of the other components was as good or better than conventional hot-pressed block.

Battelle Memorial Institute 505 King Avenue Columbus, Ohio 43201

Attention: Mr. Hugh Haynes

Subject: Battelle Memorial Institute

> Purchase Order No. S6371 Inner Cylinder Cover

Pt. No. 425798

Dear Hugh,

The enclosed drawing has certain dimensional characteristics numerically identified to conform to our Quality Control Master Drawing. This identification will help isolate discrepancies on two of the three parts we are manufacturing for the Subject Order.

We submit the following data for your evaluation, and hopefully, your approval:

Piece No. 1

Characteristic #20 .172 dim. is .165 to .169

21 .344 typical is .350 47 .151 + .0005 is .152 - .1508

66 .095 +.002 is .096 - .098

Piece No. 2

Characteristic 2 .010 is .0059 - .0167

41 .635 ±001 is .635 to .638

43 1.270 ±001 is 1.274

75 .1125 ±0005 is .1120 to .1133

Considering the experimental nature of this order we are hopeful these discrepancies may be acceptable.

We await your early disposition.

Regards, 🦪
